Robust Place Recognition with Stereo Sequences
César Cadena, Member, IEEE, Dorian Gálvez-López, Juan D. Tardós, Member, IEEE, and José Neira, Senior Member, IEEE

Abstract—We propose a place recognition algorithm for SLAM systems using stereo cameras that considers both appearance and geometric information of points of interest in the images. Both near and far scene points provide information for the recognition process. Hypotheses about loop closings are generated using a fast appearance-only technique based on the bag-of-words (BoW) method. We propose several important improvements to BoWs that profit from the fact that in this problem images are provided in sequence. Loop closing candidates are evaluated using a novel Normalised Similarity Score, that measures similarity in the context of recent images in the sequence. In cases where similarity is not sufficiently clear, loop closing verification is carried out using a method based on Conditional Random Fields (CRFs). We build on CRF-matching with two main novelties: we use both image and 3D geometric information, and we carry out inference on a Minimum Spanning Tree (MST), instead of a densely connected graph. Our results show that MSTs provide an adequate representation of the problem, with the additional advantages that exact inference is possible and the computational cost of the inference process is limited. We compare our system with the state of the art using visual indoor and outdoor data from three different locations, and show that our system can attain at least full precision (no false positives) for a higher recall (fewer false negatives).

Index Terms—Recognition, Bag of Words, Conditional Random Fields, Computer Vision, SLAM.

I. INTRODUCTION

In this paper we consider the problem of recognising locations based on scene geometry and appearance. This problem is particularly relevant in the context of large-scale global localisation and loop closure detection in mobile robotics. Algorithms based on visual appearance are becoming popular because cameras are easily available and provide rich scene detail. In recent years, it has been shown that taking geometric information also into account further improves system robustness. Most systems rely on a geometrical checking to verify spatial consistency [1]–[7].

We propose to solve the place recognition problem by using two complementary techniques, see Fig 1 (preliminary versions of this work were described in [8,9]). The first one is based on the bag-of-words method (BoW) [10], which reduces images to sparse numerical vectors by quantising their local features. This enables quick comparisons among a set of images to find those which are similar. We use a hierarchical BoW [11] with several novelties that consider the sequential nature of data acquisition. First, we define a novel normalised similarity score ($\eta$) to evaluate similarity with respect to recent images in the sequence. We also enforce a temporal consistency of the candidate matches to improve robustness. And finally, we classify the candidates into three categories according to the normalised similarity score: high confidence, unclear, and clear rejection.

Fig. 1. Scheme of our proposal applied to a scene at time $t$ in the sequence.
Unclear loop closure candidates are verified by matching the scenes with CRFs, the second technique considered. CRF-Matching is an algorithm based on Conditional Random Fields (CRFs) [12], recently proposed for matching 2D laser scans [13] and matching image features [14]. CRF-Matching uses a probabilistic model able to jointly reason about the association of features. Here we extend CRF-Matching to reason about the association of data provided by a stereo camera system in both image space and in 3D space. This allows our system to consider all information provided by a stereo pair, both near and far. As a graph structure for the CRFs in our problem, we propose the use of the Minimum Spanning Tree (MST), where vertices are the features detected in the images, and edge weights are Euclidean distances between them. Because we code near information in the 3D metric space, and far information in image coordinate space, each type of visual information is represented in a separate graph. We also propose accepting the loop closure candidates based on a normalised similarity score in terms of the likelihoods of the matched scenes, also with respect to recent images.

Our basic idea is to exploit the efficiency of BoW for detecting revisited places in real-time using only appearance (Section III-A) and the robustness of CRF-Matching to verify, only in unclear cases, that revisiting matches are correct (Section III-B).

In Section IV we analyse the performance of our system using image sequences from the RAWSEEDS project, obtained with a frontal stereo camera in both indoor and outdoor environments. These sequences contain challenging scenes, including many cases of perceptual aliasing, changes in illumination due to time of day, and dynamic environments. We compare our system with the state of the art in visual place recognition, FAB-MAP 2.0 [5,15]. Our system exhibits better precision-recall performance.

II. RELATED WORK

Place recognition using visual information has been a problem of great interest in robotics for some time. Most successful methods consider appearance or geometric information, or a combination of both. Williams et al. [16] compared three loop closure methods representative of each idea: a map-to-map method that considers mainly geometry, an image-to-image method that considers only appearance, and an image-to-map method that considers both. The best results were obtained for the image-to-image and image-to-map methods, although the image-to-map method does not scale well in large environments.

The image-to-image method considered in the work of Williams et al. was FAB-MAP, the first successful appearance-only method, proposed by Cummins and Newman [15]. FAB-MAP uses the bag-of-words (BoW) representation [10], supported by a probabilistic framework. This system proved very successful in large scale environments. It can run with full precision (no false positives), although at the expense of low recall (the rate of true positives declines). Avoiding false positives is crucial because they result in failure to obtain correct maps, but avoiding false negatives is also important because they limit the quality of the resulting maps, particularly if large loops are not detected. Geometric information has shown to be important in avoiding false positives while sacrificing less true positives. Angeli et al. [1] proposed an incremental version of BoW, using a discrete Bayes filter to estimate the probability of loop-closure. Since the Bayes filter can still exhibit false positives in cases where the same features are detected, but in a different geometric configuration, the epipolar constraint was used to verify candidate matchings. Valgren and Lilienthal [2,3] also verify topological localisation candidates using the epipolar constraint, but matching of an image is carried out against the complete image database, which can become inefficient for large environments. Regarding false negatives, Mei et al. [17] apply a query-expansion method based on the feature co-visibility matrix to enrich the information of the locations and facilitate loop detection. In the field of object retrieval, Chum et al. [18] also use a query-expansion method to perform image queries against large databases, using appearance information only. All initial candidates are re-ranked using an affine homography and then query-expansion is carried out. Currently, the performance of such query-expansion methods is heavily dependent on parameter tuning [17]. Furthermore, they do not improve the recall in cases where the image depicts a new place, or there is perceptual aliasing [5].

Other methods have shown the importance of incorporating geometric constraints to avoid false positives. Konolige et al. [7] uses a stereo pair to check for a valid spatial transformation between two pairs of matching scenes by trying to compute a valid relative pose transformation. The acceptance criteria is based on the number of inliers. A very similar strategy for geometrical checking is used by Newman et al. [6] with stereo, over the candidates provided from FAB-MAP using an omnidirectional camera. Olson et al. [4] test the spatial consistency of a set of candidate matchings by additionally considering their associated pose estimates. This requires odometry or some other source for the priors on the poses. Cummins and Newman [5] incorporated a simplified constraint check for an omnidirectional camera installed on a car in FAB-MAP 2.0. This system was tested using two extremely large (70km and 1000km) datasets. They obtain recalls of 48.4% and 3.1%, respectively, at 100% precision. Recently proposed by Paul and Newman [19], FAB-MAP 3D additionally includes 3D distances between features provided by a laser scanner. This results in higher recall for the same precision in the first urban experiment of FAB-MAP. However, the system can only make inferences about visual features in the laser range.

The place recognition problem has also been addressed using only 3D range data. Steder et al. [20] extract features from range images obtained by a 3D laser scanner and query a database in order to detect loop closures. This system has high computational requirements compared with systems based on BoWs, but higher recall is attained for the same precision. An important limitation is that this system cannot distinguish between locations with similar shape but different appearance, for example corridors, or with different background beyond the sensor’s range.

Our system follows a slightly different approach: in order to attain full precision and high recall, an improved BoW
A modified version of the one proposed by [11]. Given two vectors \( v \) and \( w \), their similarity is measured as the score \( s(v, w) \):

\[
s(v, w) = 1 - \frac{1}{2} \frac{\|v - w\|}{\|v\| \|w\|}
\]

This method is suitable for managing a large amount of images; moreover, [11] presents a hierarchical version which improves efficiency. In this version, the descriptor space clustering is done hierarchically, obtaining a visual vocabulary arranged in a tree structure, with a branch factor \( k \) and \( L \) depth levels. In this way, the comparisons for converting an image descriptor into a visual word only need to be done in a branch and not in the whole discretised space, reducing the search complexity to logarithmic. Our implementation\(^1\) of this data structure is used in this paper with \( k = 9 \), \( L = 6 \) and the \textit{kmeans++} algorithm [26] as clustering function. This configuration yielded the best performance in our tests and experiments.

## III. OUR PROPOSAL

In this section we describe the two components of our system that constitute the core of our approach: loop closing detection and loop closing verification. Our place recognition system can be summarized in algorithm 1.

### A. Loop Closing Detection

In the spirit of visual bags-of-words [10] we first represent an image of the scene as a numerical vector by quantising its salient local SURF-features [24] (see Fig. 2(a)). This technique entails an off-line stage that consists in clustering the image descriptor space (the 64-dimensional SURF space, in our case) into a fixed number \( N \) of clusters. This is done with a rich enough set of training images, which can be independent of the target images. The centres of the resulting clusters are named **visual words**; after the clustering, a **visual vocabulary** is obtained. Now, a set of image features can be represented in the visual vocabulary by means of a vector \( v \) of length \( N \). For that, each feature is associated to its approximately closest visual word. Each component \( v_i \) is then set to a value in accordance with the relevance of the \( i \)-th word in the vocabulary and the given set, or 0 if that word is not associated to any of the image descriptors. There are several approaches to measure the relevance of a word in a corpus [25]; in general, the more a word appears in the data used to create the visual vocabulary, the lower its relevance is. We use the term frequency – inverse document frequency (tf-idf) as proposed by [10].
In a general problem with bags-of-words, when comparing a vector $v$ against several others, choosing the vector $w$ whose score $s(v, w)$ is maximum is usually enough for establishing a match. However, this is not enough in our context. Ours is a special case where the acquired data are sequential. This means that vectors $v$ and $w$ are associated to instants of time $t$ and $t'$ and that we can take advantage of this fact. Furthermore, it is expected to have lots of very similar images in our problem, since they are collected close in time. In many cases the matched vector with the highest score $s$ may be not the one we are looking for. We want to distinguish those cases, but the range the score $s$ varies is very dependent on the query image and the words this contains, so that it is difficult to set a threshold that works fine in every situation. For these reasons, we define a novel metric of similarity, the *normalised similarity score* ($\eta_c$), as:

\begin{equation}
\eta_c(t, t') = \frac{s(v_t, w_{t'})}{s(v_t, v_{t-\gamma})}
\end{equation}

We normalise the score obtained from a match between $v_t$ and $w_{t'}$ with the expected score for the query vector $v_t$. The expected value for $v_t$ is the score obtained when comparing it against a very similar vector. In our case, this is the vector obtained $\gamma = 1$ s ago. If the score $s(v_t, v_{t-\gamma})$ is very small (e.g. if the robot rotated very fast and those two images were not similar at all), the normalised similarity score is not reliable. For this reason, we discard those query vectors $v_{t}$ such that $s(v_t, v_{t-\gamma}) < 0.1$. For the rest of the cases, the higher $\eta_c$ is, the more similar two images are. The effect of this normalisation is to increase the matching scores of those query images that obtain small scores $s$ because of their number of features, bringing them closer to those attaining higher $s$. Note that the normalised similarity score can be defined for any similarity score.

2) Temporal consistency: Our system takes an image at time $t$ from the stereo pair at one frame per second. The image
is converted into a bag-of-words vector $v_t$, which is stored in a set $W$. At the same time, an inverted file is maintained to save in which images each visual word is present [10]. The set $W$ and the inverted file compose our database of places already visited. The current image vector $v_t$ is compared against all the ones previously stored $W$ that have at least one word in common with $v_t$. The complexity of this operation in the worst case is linear in the number of stored vectors, but checking the common words by looking up the inverted file makes it very quick. The result is a list of matches $<v_t, w'_v>$, associated to their scores $\eta_c(t, t')$, where $w'_v$ are the vectors matched from $W$. Of these matches, those whose instants $t$ and $t'$ are too close are discarded to avoid matching images taken very close in time. We disallow matches against images taken less than 20 seconds ago. This value may depend on the length of the loops and the velocity of the robot, but we noticed this value suffices with the usual environment and platforms we use in our experiments.

To detect loops, we impose a temporal constraint. A loop candidate between images at time $t$ and $t_0$ is detected if there exist matches $<v_t, w_0>, <v_{t-1}, w_1>, <v_{t-2}, w_2>, ...$, for a short time interval of $\tau_t = 4$ seconds, that are pairwise consistent. There is consistency if the difference between consecutive timestamps $t_0, t_1, ...$, is small (i.e. within $\tau_d = 2$ seconds). These temporal values were selected according to the movement speed of the robot in our image sequences, and the expected reliability of the method.

Finally, the match $<v_t, w_{t_0}>$, with normalised score $\eta_c(t, t_0)$, is checked by a double threshold $(\alpha^-, \alpha^+)$ in order to be accepted as a loop closure. If this score is high enough (if $\eta_c(t, t_0) \geq \alpha^+$), the match is very likely to be correct, so the candidate is accepted as a loop closing. On the contrary, if this score is small (if $\eta_c(t, t_0) < \alpha^-$), the candidate is rejected. In the cases where this normalised score alone is not sufficient to ensure loop closure $(\alpha^- \leq \eta_c(t, t_0) < \alpha^+)$, verification is necessary.

**B. Loop Closing Verification**

In this section we describe the process to decide when an unclear loop closure candidate from BoW is accepted or rejected. This process is done by inferring on the data association, or matching, between SURF-points of the candidates scenes. Here we refer to SURF-point as the pixel in the image where the SURF-feature was detected. The matching is carried out using conditional random fields (CRFs), a probabilistic undirected graphical model first developed for labelling sequence data [12]. We model the scene as two graphs: the first graph ($G_{3D}$) models the near objects, i.e. those pixels with dense information from the stereo, and hence with 3D information (see Fig. 2(c) and 2(d)). And the second graph ($G_{Im}$) models the far objects from pixels without disparity information (see Fig. 2(b)). The nodes of the graphs are the SURF-points extracted before, and the edges of the graphs result from computing the minimum spanning tree (MST), according to the Euclidean distances between the pixel coordinates in the case of $G_{Im}$, and between the 3D metric coordinates in the case of $G_{3D}$.

CRFs are a case of Markov Random Fields (and thus satisfy the Markov properties) where there is no need to model the distribution over the observations [27,28]. If the neighbourhood of a node $A$ (i.e. all nodes with edges to $A$) in the graph is known, the assignment to $A$ is independent of the assignment to another node $B$ outside the neighbourhood of $A$. By definition, the minimum spanning tree connects points that are close in the measurement space, highlighting intrinsic localities in the scene. This implies: first, that the associations are jointly compatible within neighbourhoods, and second, that the compatibility is enforced and propagated from neighbourhood to neighbourhood by the edge between them.

1) **Model definition:** Instead of relying on Bayes’ rule to estimate the distribution over hidden states $x$ from observations $z$, CRFs directly model $p(x|z)$, the conditional distribution over the hidden variables given observations. Due to this structure, CRFs can handle arbitrary dependencies between the observations. This makes them substantially flexible when using complex and overlapped attributes or observations.

The nodes in a CRF represent hidden states, denoted $x = (x_1, x_2, \ldots, x_n)$, observations are denoted $z$. In our framework the hidden states correspond to all the possible associations between the $n$ features in scene A and the $m$ features in scene B, i.e. $x_i \in \{0, 1, 2, \ldots, m\}$, where the additional state 0 is the outlier state. Observations are provided by the sensors (e.g. 3D point clouds, appearance descriptors, or any combination of them). The nodes $x_i$ along with the connectivity structure represented by the undirected graph define the conditional distribution $p(x|z)$ over the hidden states $x$. Let $C$ be the set of cliques (fully connected subsets) in the graph of a CRF. Then, a CRF factorizes the conditional distribution into a product of clique potentials $\phi_c(z, x_c)$, where every $c \in C$ is a clique in the graph, and $z$ and $x_c$ are the observed data and the hidden nodes in such clique. Clique potentials are functions that map variable configurations to non-negative numbers. Intuitively, a potential captures the “compatibility” among the variables in the clique: the larger a potential value, the more likely the configuration. Using the clique potential, the conditional distribution over hidden states is written as:

$$p(x|z) = \frac{1}{Z(z)} \prod_{c \in C} \phi_c(z, x_c)$$

where $Z(z) = \sum_{\tilde{x}} \prod_{c \in C} \phi_c(z, x_c)$ is the normalising partition function. The computation of this function can be exponential in the size of $x$. Hence, exact inference is possible for a limited class of CRF models only, e.g. in tree-structured graphs.

Potentials $\phi_c(z, x_c)$ are described by log-linear combinations of feature functions $f_c$, i.e., the conditional distribution (3) can be rewritten as:

$$p(x|z) = \frac{1}{Z(z)} \exp \left( \sum_{c \in C} w_c^T \cdot f_c(z, x_c) \right)$$

where $w_c$ a weight vector, which represents the importance of different features for correctly identifying the hidden states. Weights can be learned from labelled training data.
2) **Inference:** Inference in a CRF estimates the marginal distribution of each hidden variable \( x_i \), and can thus determine the most likely configuration of the hidden variables \( x \) (i.e., the maximum a posteriori, or MAP, estimation). Both tasks can be solved using belief propagation (BP) [29], which works by transmitting messages containing beliefs through the graph structure of the model. Each node sends messages to its neighbours based on the messages it receives and the clique potentials.

3) **Parameter learning:** The goal of parameter learning is to determine the weights of the feature functions used in the conditional likelihood (4). CRFs learn these weights discriminatively by maximising the conditional likelihood of the training data, which is given by the product of all local likelihoods \( p(x_i | MB(x_i)) \); where MB(\( x_i \)) is the Markov Blanket of variable \( x_i \), which contains the immediate neighbours of \( x_i \) in the CRF graph. Optimisation of this pseudo-likelihood is performed by minimising the negative of its log, resulting in the following objective function:

\[
L(w) = - \sum_{i=1}^{n} \log p(x_i | MB(x_i), w) + \frac{w^T w}{2 \sigma^2_w} \tag{5}
\]

The rightmost term in (5) serves as a zero-mean Gaussian prior, with variance \( \sigma^2_w \), on each component of the weight vector.

The training data are labelled using RANSAC [30] over the best rigid-body transformation in 6DoF [31] for \( G_{3D} \) and over the fundamental matrix for \( G_{1m} \), after SURF matching of two consecutive scenes.

4) **Feature description:** The CRF matcher can employ arbitrary local features to describe shape, image properties, or any particular aspect of the data. Our features describe differences between shape (only for \( G_{3D} \)) and appearance (for both graphs) of the features. The local features we use are the following:

- **Shape difference:** These features capture how much the local shape of dense stereo data differs for each possible association. We use the geodesic, PCA and curvature distance.

  The **geodesic distance**, defined as the sum of Euclidean distances between points in the minimum spanning tree, provides information about the density of the neighbourhood of each node of the graph. It can be calculated for different neighbourhoods representing local or long-term shape information. Given points \( z_{A,i} \), \( z_{B,j} \) and a neighbourhood \( k \), the geodesic distance feature is computed as:

\[
f_{geo}(i,j,k, z_{A,i}, z_{B,j}) = \left\| \sum_{l=1}^{j+k-1} \| z_{A,l+1} - z_{A,l} \| - \sum_{l=j}^{j+k-1} \| z_{B,l+1} - z_{B,l} \| \right\| \tag{6}
\]

where \( i \) and \( j \) correspond to the hidden state \( x_i \) that associate the feature \( i \) of the scene A with the feature \( j \) of the scene B. The neighbourhood \( k \) of \( x_i \) in the graph corresponds to all the nodes separated \( k \) nodes from \( x_i \). In our implementation, this feature is computed for \( k \in \{1, 2, 3\} \). A similar feature is used to match 3D laser scans in [32].

We also use Principal Component Analysis over the dense 3D point cloud that is contained within some spheres centred in the graph nodes (textured points in Fig. 2(d)). The radius of these spheres is given by the keypoint scale provided by the SURF extractor. The **PCA distance** is computed as the absolute difference between the variances of the principal components of a dense point cloud \( z_{A,i}^{pca} \) in scene A and \( z_{B,j}^{pca} \) in scene B:

\[
f_{PCA}(i,j, z_{A,i}^{pca}, z_{B,j}^{pca}) = \left\| z_{A,i}^{pca} - z_{B,j}^{pca} \right\| \tag{7}
\]

Another way to consider local shape is by computing the difference between the curvatures of the dense point clouds. This feature is computed as:

\[
f_{curv}(i,j, z_{A,i}^{pca}, z_{B,j}^{pca}) = \left\| z_{A,i}^{pca} - z_{B,j}^{pca} \right\| \tag{8}
\]

where \( z_c = \frac{s_1 s_3}{s_1 + s_2 + s_3} \), and \( s_1 \geq s_2 \geq s_3 \) are the singular values of the point cloud of each node.

- **Visual appearance:** These features capture how much the local appearance from the points in the image differs for each possible association. We use the **SURF distance**. This feature calculates the Euclidean distance between the descriptor vectors for each possible association:

\[
f_{SURF}(i,j, z_{A,i}^{descr}, z_{B,j}^{descr}) = \left\| z_{A,i}^{descr} - z_{B,j}^{descr} \right\| \tag{9}
\]

Ramos et al. [14] also include as features the distances between the individual dimensions of the descriptor space. In our training and validations data we do not find a significant improvement in the accuracy of the labelling, and this greatly increases the size of the weight vector.

All previous features described are unary, in that they only depend on a single hidden state \( i \) in scene A (indices \( j \) and \( k \) in the features denote nodes in scene B and neighbourhood size). In order to generate mutually consistent associations it is necessary to define features, over the cliques, that relate the hidden states in the CRF to each other.

- **Pairwise distance:** This feature measures the consistency between the associations of two hidden states \( x_i \) and \( x_j \), and observations \( z_{A,i} \), \( z_{A,j} \) from scene A and observations \( z_{B,k} \) and \( z_{B,l} \) in scene B:

\[
f_{pair}(i,j,k,l, z_{A,i}, z_{B,j}) = \left\| \| z_{A,i} - z_{A,j} \| - \| z_{B,k} - z_{B,l} \| \right\| \tag{10}
\]

The \( z_A \) and \( z_B \) are in metric coordinates for \( G_{3D} \), and in pixels for \( G_{1m} \).

5) **Loop closure acceptance:** We use the CRF matcher stage over the loop closing candidates provided by the BoW stage. Then, we compute the negative log-likelihood (\( \Lambda \)) from the MAP associations between the scene in time \( t \), against the loop closing candidate in time \( t' \), \( \Lambda_{t,t'} \), and the scene in \( t - \gamma \), \( \Lambda_{t,t-\gamma} \), \( \gamma = 1s \).

The negative log-likelihood \( \Lambda^{3D} \) of the MAP association for \( G_{3D} \) provides a measure of how similar two scenes are in terms of close range, and \( \Lambda^{1m} \) for \( G_{1m} \) in terms of far range. Thus, in order to compare how similar the current scene is with the scene in \( t' \), \( \Lambda_{t,t'} \), with respect to how similar the

current scene is with the scene in \( t - \gamma \), \( \Lambda_{t,t-\gamma} \), we use again a normalised similarity score as:

\[
\eta_{\mathcal{G}} = \frac{\Lambda_{t,t}^G}{\Lambda_{t,t-\gamma}^G}
\]

(11)

where \( \mathcal{G} \) indicates the graph.

Score \( \eta_{\mathcal{G}} \) is compared to \( \beta_{\mathcal{G}} \), a control parameter of the level of similarity we demand for \((t, t - \gamma)\), where a smaller \( \beta \) means a higher demand. By choosing different parameters for near and far information we can make a balance between the weight of each in our acceptance.

IV. EXPERIMENTS

We evaluated our system with the public datasets from the RAWSEEDS Project [33]. The data were collected by a robotic platform in different static and dynamic environments. We used the data corresponding to the stereo vision system with 18cm of baseline. These are b/w images (640x480px) taken at 15 fps with the Videre Design STH-DCSGVAR system.

We used a static dataset depicting a mix of indoor and outdoor areas to perform the offline stages of our system. These entail the training of the bag-of-words vocabulary and the learning of the CRF feature weights. We then tested the whole system in three datasets: static indoors, static outdoors and dynamic mixed. These three datasets along with the training one were collected on different dates and in two different campuses. The trajectory of the robot in the outdoor and mixed datasets has some overlap in location with the dataset used for training; this is not the case with the indoor dataset, which was collected in a different campus. Please refer to the RAWSEEDS Project [33] for further details.

In addition, in order to evaluate the final configuration of our system, we used the Malaga parking lot 6L dataset [34]. This is a public dataset with different vehicle, stereo camera (AVT Marlin F-131C model) and configuration (1024x768px at 7.5fps and 86cm of baseline), than those in the RAWSEEDS Project. Table I shows the information related to these datasets.

In this experimental evaluation section, we first show the effect of each of system components in the loop detection stage in IV-A. Then in IV-B, we compare the use of the Delaunay triangulation and MST during the CRF learning process, and also the influence of each feature proposed above. Finally, we show the performance of our full system in the aforementioned datasets in IV-C – IV-E.

A. Loop detection stage

We used 200 images uniformly distributed in time from the training dataset to create a bag-of-words vocabulary tree with \( k = 9 \) branching factor and \( L = 6 \) depth levels.

We started evaluating how each step of our loop detection stage affects the correctness of the resulting matching candidates. We compared the effectiveness of the score \( s \) and \( \eta_c \) when used with both our proposed BoW algorithm (with temporal consistency) and a simple bag-of-words approach. This simple technique consists in selecting the matching image that maximises the score for a given query. In Fig. 3 we show the precision-recall curves yielded by each configuration as varying the minimum required score. We can see that our BoW with temporal consistency and \( \eta_c \) score obtained the highest recall for 100% precision in the datasets.

Our BoW with temporal consistency outperforms the simple bag-of-words approach. This is specially noticeable in the outdoor dataset, where the simple is not able to achieve 100% precision, so that final results would be hardly reliable. The simple bag-of-words approach failed in this dataset because distant objects, such as buildings, are visible in many images, causing incorrect matches. Requiring temporal consistency
reduces these cases because it is unlikely to obtain several consecutive matches with the same wrong place. This makes clear the usefulness of the temporal consistency, as also reported before in [8].

Regarding the score, \( \eta_c \) attained higher recall for full precision than the score \( s \) both indoors and outdoors. In the indoor dataset, the behaviour of both scores with our BoW approach with temporal consistency was similar, but the advantage of \( \eta_c \) is clear with the simple approach, when just the match with the maximum score is chosen. This shows that \( \eta_c \) is able to provide more discriminative scores than \( s \).

### B. Loop verification stage

With the same 200 images used for training the bag-of-words vocabulary, we learned the weights for the CRF matcher. For this, we obtained the SURF-features from the right image in the stereo rig and selected those with 3D information from the dense point cloud given by the stereo system. Then, we ran a RANSAC algorithm over the rigid-body transformation between the images at time \( t \) and \( t - \delta_t \). Since the stereo system has high noise in the dense 3D information, we selected \( \delta_t = 1/15s \). The same procedure was done over the remaining SURF features with no 3D information, where we obtained the labels by calculating the fundamental matrix between the images. These two steps resulted in an automatic learning of the CRF labels. Although this automatic labelling can return some outliers, the learning algorithm has demonstrated being robust in their presence. We used the optimisation based on the BFGS quasi-Newton method provided by MATLAB to find the weights that minimised the negative log pseudo-likelihood. In both \( G_{3D} \) and \( G_{IM} \), the weights obtained suggested that the most relevant features in the CRF matcher were \( f_{SURF} \) and \( f_{pair} \).

**Delaunay vs. MST:** In order to verify that the accuracy of the data association using the CRFs as proposed in this paper is not negatively affected by using MST instead of the Delaunay triangulation, a 10-fold cross-validation procedure was carried out. For this, the pairs of images used for learning the weights, both in 3D and image, were randomly permuted and equally divided into ten groups. Nine groups were used for training, and the 10th, for validation (training and validation data are mutually exclusive). This process was repeated 10 times and the evaluation metrics were computed across folds for all the validation trials.

The 10-fold cross validation was performed for \( G_{3D} \) and \( G_{IM} \), both with the Delaunay triangulation and the minimum spanning tree graph structures. The results of the statistic test in the accuracy of the matching with respect to the labelling given are shown in Table II. The results in the validation data suggest that there is not statistical evidence to favour the Delaunay triangulation as graph structure for our CRF matching processes over the MST. These results agree with the conclusion drawn by Quattoni et al. [21].

**Relative importance of features:** The influence of each feature proposed in the CRF-Matching is studied in the learning stage. The set used for learning was randomly divided into two 60-40% groups, 60% for training and 40% for validation. The learning was then carried out with all the features but one each time. The accuracy in data association is shown in Table III for both graphs.

The accuracy obtained in each case shows that \( f_{SURF} \) and \( f_{pair} \) are the most relevant features in the inference process. However, in the validation set for \( G_{3D} \), we lose about 2% in the mean accuracy of data association when we remove any other feature. This is a short analysis about the influence of each feature in the inference process that could be extended. For instance, we could analyse many more combinations by adding or removing more than one feature.

Although we have considered a certain set of features in our system, CRFs are amenable to the use of different or additional features that might become available through other sensors or sensing modalities.

### C. Full system

In this section we analyse the performance of our detection and verification stages put together. In addition, we compare our system with the state-of-the-art technique FAB-MAP 2.0 [5]. The FAB-MAP software\(^2\) provides some predefined vocabularies. We used the FAB-MAP indoor vocabulary for our indoor dataset and the FAB-MAP outdoor vocabulary for the mixed and outdoor datasets. This technique has a set of parameters to tune in order to obtain the best performance in each experiment. We give a short description of the parameters in the appendix A (for further details please see [15]). We chose two parameter sets in order to obtain different results (see Table IV):

- The default parameter set that is provided by the authors.
- The probability threshold \( p \) is taken as 0.99, considering obtaining as few false positives as possible. When we

---

\(^2\)The software and vocabularies were downloaded from http://www.robots.ox.ac.uk/~mobile/
use this configuration, we check the results yielded by FAB-MAP for geometrical consistency.

- A modified parameter set is tuned to obtain the maximum possible recall at full precision. The idea behind of this tuning is to use as place recognition system only the FAB-MAP 2.0, without geometrical verification. For the outdoor dataset this parameter set is the same than the default set, only changing the probability threshold.

We filter the results of FAB-MAP 2.0 when using the default configuration with a geometrical checking. Since the last available version of the FAB-MAP software does not implement the geometrical checking described by Cummins and Newman [5], we implemented a geometrical checking (denoted GC) based on epipolar geometry. This epipolar constraint consists in computing the fundamental matrix (by using RANSAC and the 8-point algorithm [35]) between two matched images. This test is passed if a well conditioned fundamental matrix can be obtained.

Firstly, we compared the correctness of our BoW detector with that of FAB-MAP 2.0, both with no geometrical verification. Fig. 4 shows the precision-recall curves resulting in the three RAWSEEDS datasets. We obtained them by varying the minimum confidence value expected for a loop closure candidate of BoW, $\alpha^-$ (with fixed minimum confidence level for a trusted loop closure $\alpha^+ = 0.6$), and the probability of acceptance $p$ of FAB-MAP 2.0. We can observe that the curve of BoW dominated those of FAB-MAP 2.0, even without geometrical checking. As it was expected, when we choose carefully the parameters of FAB-MAP 2.0, the results we obtain are much better than when using the configuration by default. This is specially noticeable in the indoor dataset, where there were false positives in all the cases with the default parameters. This is due to the several similar-looking corridors and libraries this dataset presents.

Later, we added the geometrical verification stage to BoW and FAB-MAP 2.0 and compared the results of our system (BoW with CRF-Matching) and other approaches: FAB-MAP 2.0 with GC, and BoW with GC. We show an example of the results obtained in the indoor dataset in Fig. 5. These were obtained by varying $\alpha^-$ and $p$, with $\alpha^+ = 0.6$. For our system, we set the $\beta$ parameters of the CRF matcher in order to obtain

![Fig. 4. Precision and Recall without CRF verification or epipolar constraint with BoW and FAB-MAP 2.0 with two parameter sets.](image)

![Fig. 5. Precision-recall curves for the indoor dataset. In each curve the working point is marked, as in the Table IV and Table V. We also show our BoW stage with geometrical checking (GC) as verification. The GC checks the epipolar constraint with RANSAC. Note that FAB-MAP 2.0 with the modified configuration needs no GC.](image)

| Table IV: FAB-MAP 2.0 - Parameters for the Experiments |
|-------------|-------|-------|-------|
| $p$ | default | Outdoor | Indoor | Mixed |
| $P(obs|exist)$ | 0.99 | 0.96 | 0.5 | 0.3 |
| $P(obs|exist)$ | 0.9 | 0.9 | 0.9 | 0.5 |
| $P(newplace)$ | 0.9 | 0.9 | 0.9 | 0.5 |
| $\sigma$ | 0.9 | 1.0 | 1.0 | 1.0 |
| Motion Model | 0.8 | 0.8 | 0.8 | 0.6 |
| Blob Resp. Filter | 25 | 25 | 25 | 25 |
| Dis. Local | 20s | 20s | 20s | 20s |

| Table V: Our System - Parameters for the Experiments |
|-------------|------|------|------|
| $\alpha^+$ | Indoor | Outdoor | Mixed |
| $\alpha^-$ | 0.6 | 0.6 | 0.6 |
| $\beta_{iD}$ | 1.0 | 1.0 | 1.5 |
| $\beta_{im}$ | 4s | 4s | 4s |
| $\tau_d$ | 2s | 2s | 2s |
| Min $n_{t-\tau}$ | 1.0 | 1.0 | 0.1 |
| Dis. Local | 20s | 20s | 20s |
100% precision. We performed this test to compare recall with the state of the art. In view of results shown in Fig. 4, we selected the working value \( \alpha = 0.15 \). Since these datasets are fairly heterogeneous, we think these \( \alpha \) values can work well in many situations. It might depend on the vocabulary size, though. All the parameters used are shown in Table V.

The results of FAB-MAP 2.0 over the datasets are shown in Figs. 6(a), 7(a) and 8(a) for the default set of parameters plus the geometrical checking with the epipolar constraint, and in Figs. 6(b), 7(b) and 8(b) for the modified set of parameters. Please, note that FAB-MAP 2.0 with the modified configuration does not need geometrical verification, since we selected the parameters aiming to obtain no false positives.

Again, as expected with the modified parameters, FAB-MAP 2.0 obtained greater recall at full precision than with the parameters by default, although, some loop closures were not detected. We detail some cases: in the Indoor dataset, Fig. 6(a), the big area on the beginning of the map (start-end), especially important in the experiment because if no loop is detected in that area, a SLAM algorithm could hardly build a correct map after having traversed such a long path (around 300 metres). Outdoors, as shown in Figs. 7(a) and 7(b), the biggest loop was missed in the starting and final point of the experiment, in the marked area (O1) in the map. An example of a false negative in this area is shown in Fig. 10(a). This dataset is challenging due to the illumination and blurring present in the
images. And this entails an added difficulty for FAB-MAP since the significant overlap of distant objects between consecutive images decreases its discriminative ability [36]. For the experiment in the dynamic mixed environment, important loop closures were missed again, e.g. M1 and M2 areas in Fig. 8(a). Examples of those false negative cases are shown in Figs. 10(b) and 10(c). In the false negative cases that we show in Fig. 10, both configurations of FAB-MAP 2.0 reported a probability of new place greater than 0.999.

In order to show the improvements of our loop closure verification stage, we checked the candidates given by BoW with the same GC technique we described above. The results are shown in Figs. 6(c), 7(c) and 8(c). In Fig. 6(c) all the loop closure areas were detected but with too many false positives due to the perceptual aliasing (see Fig. 9); this is disastrous for any SLAM algorithm. In the outdoor and mixed datasets the precision was 100%, sacrificing recall and, more important, the detection of loop closure areas. As we can see in Fig. 5 we can tune the parameters of BoW+GC to attain full precision, but at the cost of sacrificing recall. This also makes the performance of this system not good and stable across environments and conditions.

The results of our system over the datasets are shown in Figs. 6(d), 7(d) and 8(d), and the comparative statistics of all experiments is made in Table VI. In the indoor experiment we can detect all the loop closure areas at 100% precision. In the outdoor and mixed datasets we keep full precision, higher recall level and most of the loop closure areas detected.

Our system detected successfully the loops of Fig. 10 as true positives. The three cases shown were verified by the CRF stage. Our CRF matcher reports the follow η scores: in O1, Fig. 10(a), $\eta_{1D} = 1.24$ and $\eta_{IM} = 1.37$, in M1, Fig. 10(b),

the graphs includes computing the MSTs, the corresponding features and the inference for each one. The time for the whole system includes computing the 3D point cloud from the disparity map and writing and reading the SURF descriptors and point clouds on disk.

### E. No hands test

After obtaining the best results in the different datasets of the RAWSEEDS Project comparatively, we tested our system over a different dataset, the Malaga parking lot 6 [34]. As before, we carry out the place recognition task at 1fps. This dataset, as the indoor one above, was collected in a completely different location from the one where our training images were acquired. The main challenge is to test our system with the configuration already used in the previous experiments on a different vehicle and stereo camera system.

For that, we kept the same vocabulary and CRFs’ weights, as well as the parameters used in the Outdoor dataset, as shown in Table V. In order to compare the results, we ran FAB-MAP 2.0 with the configuration that obtained better result for the outdoors experiment, and also with the default parameter set, \( p = 0.99 \), and filtering the results with the epipolar constraint GC as above.

The results over the Malaga parking lot are shown in Fig. 11 and in Table VIII. With no changes in our system we attain full precision despite the increased speed of this vehicle. Using FAB-MAP with the configuration for best performance in the outdoors experiment, we can obtain higher recall here, but precision falls down to 42%, unacceptable for any SLAM system. If we use the configuration that exhibited bad performance in recall in the outdoors experiment, FAB-MAP 2.0 def. plus GC, attains higher recall compared to our system (68% vs. 42%); both methods find 4 out of 5 loop closure zones. This makes our system more stable across different environments and conditions. We show in Fig. 12 two examples of those loops found by one and not by the other, Ma1 and Ma2.

Note in Fig. 11(c) that FAB-MAP alone has bad performance. It returns a large number of detections, more than half false loops. The increase in the number of alarms as compared with the RAWSEEDS experiments is due to the higher speed of the vehicle, 2.6 m/s vs. 0.8 m/s (see Table I). This results in less overlap between consecutive processed frames, increasing the maximum values of the probability distribution over the sequence. Still, it is susceptible to perceptual aliasing due to overlapping in the far information. This is corrected with GC because this dataset does not suffer from strong perceptual aliasing in near information, in contrast with the indoor dataset, Fig. 9.

### D. Timing

The on-line system runs at 1 fps. We have a research implementation in C++ using the OpenCV library. In Table VII we show the average and maximum times for each stage of the system on a 2.3 GHz IntelCore i3 CPU M350 and 4GB of RAM. For the whole system, the average and the maximum times were computed only when all the stages were executed. Note that the maximums for each stage happened in different cases. That is more evident in the inference process for \( G_{3D} \) and \( G_{lm} \): when an image provides more 3D points, less background information remains. In an image, the number of nodes and hidden states between \( G_{3D} \) and \( G_{lm} \) are complementary. The execution time reported for the CRFs in
Fig. 11. Loops detected by our system and FAB-MAP 2.0 in the Malaga parking lot dataset. Black lines and triangles denote the trajectory of the robot; light green lines, actual loops. In (a) high confidence detections (light blue) are accepted and unclear detections (magenta) are subject to verification. In (c) detections with $p = 0.99$ (default) are in dashed light blue, detections with $p = 0.96$ (mod.) are magenta. Detections with $p = 0.99$ which are verified with GC are shown in (d). In (b) and (d), deep blue lines denote true loops detected.

Fig. 12. Cases marked in 11(b) and 11(d) from Malaga dataset. These correspond to loops found by one and not by the other method.

Our loop closing detection stage discriminates better, still detecting the most of loop closure zones, see Fig. 11(a). As expected, our verification stage correctly decides over the unclear cases (magenta lines in Fig. 11(a)). The final result of our full system is shown in Fig. 11(b).

V. CONCLUSIONS AND FUTURE WORK

We have presented a system that combines two powerful matching algorithms, bag-of-words and conditional random fields, to robustly solve the place recognition problem with stereo cameras. We have evaluated our place recognition system in different environments (indoor, outdoor and mixed) from public datasets. In all cases the system can attain 100% precision (no false positives) with higher recall than the state of the art (less false negatives), and detecting the most (especially important) loop closure zones.

No false positives means that the environment model will not be corrupted, and less false negatives means that it will be more precise. The important lesson that we can learn from this is that we must always apply a verification stage over detected loops based on appearance. As we have seen in situations of perceptual aliasing our verification stage with the CRF matcher is more robust than the geometrical checking using the epipolar constraint.

As mentioned in [36], the effectiveness of FAB-MAP decreases when the camera looks forward, because FAB-MAP models the environment as “a collection of discrete and disjoint locations” [15]. However, in our experiments the stereo camera system faces forward, and distant objects (e.g., buildings in outdoor scenes) persist for many frames, making scenes overlap and be less discriminative. This causes the matching probability mass of FAB-MAP to be flattened over the scenes. It is easier for our system to overcome those cases because our normalised similarity scores ($\eta_c, \eta_{3D}, \eta_{im}$) for matching acceptance are computed at each frame and take into account the similarity between consecutive frames.

By using jointly the CRF-Matching algorithm over visual near 3D information (here provided by stereo vision, but also possible with range scanners, etc.) and far information, we have demonstrated that challenging false loop closures can be rejected. Furthermore, CRF-Matching is also able to fuse any other kind of information, such as image colour, with ease.

Our place recognition system is able to run in real time, processing scenes at one frame per second. In most cases, after extracting the SURF features (max. $300\, ms$), our system only takes $11\, ms$ to detect if there are possible loop closures, and $300\, ms$ to check them when necessary. We are considering the use of cheaper feature extractors that can speed up this process without a negative impact in precision and recall.

In our experiments, the best $\beta$ thresholds for acceptance of the CRF matching turned out to be clearly different for indoor and for outdoors scenarios. These parameters will also depend on the velocity of motion, mainly because we use images from the previous second as reference in the comparisons. Incorporating the computation of these thresholds as part of the
learning stage would also make the system more flexible. Nevertheless, our system has demonstrated a stable performance, always at full precision, for different environments, cameras and conditions. Systems such as simple BoW or FAB-MAP, both aided by GC, can obtain good results if adequately tuned in each case. However, the same configuration can result in very poor performance in others.

An important line of future work is addressing the place recognition problem over time. Our system performs well in multi-day sessions using parameters learned in different months, and this is also true of alternative systems such as FAB-MAP. The environment can also change during the operation in the same session (see Fig. 10). Our algorithm is also able to detect places revisited at different times of day, while alternative systems sometimes reject them in order to maintain high precision.

Several extensions are possible for operation in longer periods of time. The vocabulary for the BoW has shown to be useful in different environments, which suggests that a rich vocabulary does not require frequent updates. The learned parameters in the CRF stage can be re-learned in sliding window mode depending on the duration of the mission. The system will then be able to adjust to changing conditions. In cases of periodical changes, such as times of day or seasons, we will need to maintain several environment models and selecting the most appropriate for a given moment of operation.

APPENDIX

FAB-MAP PARAMETERS DESCRIPTION

The parameters that we have modified are the following ones (for further details please see [15] and [5]):

- \( p \): Probability threshold. The minimum matching probability required to accept that two images were generated at the same place.
- \( P(\text{obs | exist}) \): True positive rate of the sensor. Prior probability for detecting a feature given that it exists in the location.
- \( P(\text{obs | ¬exist}) \): False positive rate of the sensor. Prior probability for detecting a feature given that it does not exist in the location.
- \( P(\text{newplace}) \): Probability for new place. Prior probability to determine whether the last image is a new place.
- \( \sigma \): Likelihood smoothing factor. Factor for smoothing the likelihood values through consecutive places.
- **Motion Model**: Model Motion Prior. This biases the matching probabilities according to the expected motion of the robot. A value of 1.0 means that all the probability mass goes forward, and 0.5 means that probability goes equally forward and backward.

- **Blob Resp. Filter**: blob response filter. All the SURF points with a blob response below this threshold are discarded.

- **Dis. Local**: Disallow \( N \) local matches. Set the prior to be zero on the last \( N \) places. We use the same parameter in our system during the BoW stage for not producing matches against the last \( N \) scenes.
